Canine Demodicosis: Overview & Update

Katherine A. Doerr-Siegfried, DVM, DACVD
Veterinary Dermatology Center
Maitland, Florida

Canine demodicosis is an inflammatory condition of the skin caused by increased numbers of *Demodex* spp mites that are normally present in low numbers in the hair follicles and sebaceous glands. At least 2 different species of mites (ie, *D canis*, *D injai*) are responsible for canine demodicosis. *D cornei* was once considered a separate species, but recent literature suggests it is a variant of *D canis*.

Clinical signs include patchy to diffuse alopecia, erythematous papules, pustules, and comedones. Some patients, especially those infested with *D injai*, may have severe seborrhea oleosa. Secondary infections with bacteria and/or yeast are common and may result in more severe lesions. (See Figure 1.)

Presentation can be localized or generalized. Localized demodicosis typically is limited to less than 6 patchy alopecic regions on the head or limbs, whereas the

Demodicosis can occur in any canine breed, but some are more frequently diagnosed.
Diagnosis

Canine demodicosis is diagnosed through microscopic observation of mites in deep skin scrapings (see Figure 4) and/or trichograms. Deep skin scrapings are obtained by scraping the skin in the direction of the haircoat with a dull surgical blade or a spatula until capillary oozing is obtained. The deep skin scraping or trichogram is positive when fusiform eggs, 6- or 8-legged larvae, 8-legged nymphs, or 8-legged adults are seen. D canis adult mites typically are 40 × 250-300 µm with a moderately long tail. D injai adult mites are approximately 40 × 350 µm with a longer tail. When pododemodicosis or chronic fibrosing lesions are present, or the patient is a shar-pei, mites may be difficult to obtain by skin scraping and a skin biopsy may be required for diagnosis.

In patients with adult-onset generalized demodicosis, additional diagnostics (eg, CBC, serum chemistry profile, thyroid function tests) may be required to identify underlying diseases that can suppress the immune system (eg, hypothyroidism, hyperadrenocorticism, malnutrition, neoplastic disease).

*The only labeled treatment is amitraz every 2 weeks. The treatment plans recommended in this table are extra-label but are supported by research and the author’s personal experience.*
Treatment

Localized demodicosis may resolve without treatment within 2 months. In breeding dogs, treatment should be withheld initially to determine whether the condition will resolve on its own or progress to generalized demodicosis. If progression occurs, the dog should not be used for breeding because it may pass the disease to subsequent generations.

In the United States, amitraz dip is the only product licensed to treat demodicosis. Extra-label treatments such as macrocyclic lactones (eg, avermectins, milbemycins) are used more often than amitraz because administration is easier and more convenient. These products should not be used in breeds susceptible to the $ABCB1$-$1\Delta$ ($MDR1$) gene mutation. Examples of macrocyclic lactones include oral ivermectin or doramectin, topical moxidectin, and oral milbemycin. More recently, the isoxazoline class of parasiticides (eg, afoxolaner, fluralaner, lotilaner, sarolaner) has shown promise as an extra-label option. (See Table 1, page 23.)

Patients should be monitored with monthly deep skin scrapings from the 3 to 5 most severely affected areas, with treatment continuing for 30 days after the second negative monthly deep skin scrapings. A skin scraping is considered negative when no dead or live mites are observed. A patient is not considered “cured” until 1 year past the last negative deep skin scraping. Juvenile-onset demodicosis has a higher chance of being cured if the patient has no underlying health concerns. Patients with adult-onset demodicosis may require chronic therapy unless an underlying disease process is discovered and treated.

Demodicosis Talking Points

Following are the key points to communicate to clients:
- Juvenile-onset canine demodicosis is more likely to be localized and respond to appropriate treatment or resolve without medical intervention.
- Juvenile-onset generalized demodicosis can be hereditary, and breeding animals should be neutered.
- Underlying conditions should be considered when lesions occur for the first time in patients older than 4 years of age.
- Treatment may fail if an underlying condition and/or secondary skin infection is not treated concurrently or if therapy is discontinued too early.
- The patient is considered cured if a negative deep skin scraping is obtained 1 year after the last negative deep skin scraping.
- Approximately 10% of patients cannot be cured, and clients must be advised of this possibility and the available options for long-term therapy.

Conclusion

The veterinary team should be knowledgeable about this disease for the sake of clients and patients. (See Demodicosis Talking Points.) Demodex mites are natural inhabitants of dogs’ skin and sebaceous glands. A weakened immune system can allow mite populations to increase, resulting in alopecia, erythema, and scabbing. Localized and generalized forms of canine demodicosis can occur, and onset can start at less than 1 year of age (ie, juvenile-onset) or older than 4 years of age (ie, adult-onset). Localized demodicosis may resolve without treatment, whereas adult-onset demodicosis is often associated with an underlying condition that requires concurrent therapy.
Fifty percent of adult-onset demodicosis patients have an underlying condition, typically a disease that suppresses the immune system.

KATHERINE A. DOERR-SIEGFRIED, DVM, DACVD, is a board-certified dermatologist who currently works at a private dermatology practice in Florida. She also works for Veterinary Information Network as an online dermatology consultant. She has encountered various dermatologic diseases from many parts of the United States as her veterinary training took her from graduation from University of Florida to an internship at the University of Pennsylvania, to a residency at the University of California, Davis. Katherine is an active member of the American Academy of Veterinary Dermatology, AVMA, and local veterinary medical associations. She has also held chair positions in the American College of Veterinary Dermatologists.

FUN FACT: In her spare time, Katherine enjoys surfing, cycling, and spending time with her family.
